A radiographic image is created by exposing the patient to penetrating radiation, and detecting the radiation transmitted through the patient using an imaging device. The imaging device converts the radiation to optical signals that can be processed to form an image. The radiation may be monoenergetic, polyenergetic, pulsed, continuously emitted, or scanned. For example, high-pitch (high-energy) radiation sources may be used in radiography

---

of small structures in the body (e.g., micro-CT, micro-CT angiography (CTA), small animal micro-CT, or hybrid imaging applications), and may allow CT-like spatial resolution with much smaller detector systems, but at reduced X-ray energy (e.g., 8 keV at 70 mA). The X-ray energy or dose required in an imaging system may be estimated using the equation:  $\text{dose} = \text{convolution of kerma} = \text{flux} [\mu\text{Gy/pulse} \times \text{ms}] = \text{flux/aper} \text{ture} [\mu\text{Gy/pulse/cm}^2] \times \text{thickness} [\text{cm}] = \text{conversion of Dose} [\text{cGy/mAs}]/\text{mA}$
